1 Installation of package

The latest development version of the package can be installed using `remotes::install_github("calebong/mcst" dependencies = TRUE)`

```
require(remotes)
remotes::install_github("calebong/mcst", dependencies = TRUE)
```

2 Data Preparation

2.1 Portfolio Assets

For illustration we use the following packages to download 10 stocks from Yahoo finance at a daily frequency. The returns are then aggregated to weekly returns. These form the **endogenous** assets - the holdings to be simulated.

```
# simple function to convert class xts to dataframe
xts_to_dataframe <- function(xts_obj, column_names = NULL) {
  dates <- zoo::index(xts_obj)
  df    <- as.data.frame(xts_obj)
  df    <- cbind(date = as.Date(dates), df)
  if (!is.null(column_names)) names(df)[-1] <- column_names
  rownames(df) <- NULL
  df
}
```

```
# load in the libraries to get sample stocks data
library(tidyverse)
library(quantmod)
library(lubridate)

tickers <- c("NVDA","TSM","JPM","AXP","LMT","BA","UAL","XOM","NGG","PG")

out <- map(tickers, function(.x) {
  getSymbols(.x, from = "2010-01-01", to = Sys.Date(),
             src = "yahoo", auto.assign = FALSE) %>%
    xts_to_dataframe() %>%
    dplyr::select(1, 7) %>% #quickly select date and adjusted prices
    rename(Price = 2)
})
names(out) <- tickers

out_wide <- out %>%
  enframe() %>%
  unnest(cols = c(value)) %>%
  pivot_wider(names_from = "name", values_from = "Price")

weekly_returns <- out_wide %>%
  pivot_longer(cols = -date, names_to = "sector", values_to = "price") %>%
```

```r
  mutate(week = floor_date(date, unit = "week")) %>%
  group_by(sector, week) %>%
  summarise(price_week_end = last(price), .groups = "drop") %>%
  group_by(sector) %>%
  arrange(week) %>%
  mutate(weekly_return = price_week_end / lag(price_week_end) - 1) %>%
  ungroup() %>%
  filter(!is.na(weekly_return)) %>%
  dplyr::select(week, sector, weekly_return) %>%
  pivot_wider(id_cols = week, names_from = sector, values_from = weekly_return)
```

2.2 Exogenous Instruments

SPY (S&P 500 ETF - quick proxy for S&P 500 Index) and Crude Oil futures (`CL=F`) are downloaded separately as **exogenous** instruments. These carry zero portfolio weight and are used only as shock transmission channels in the stress-testing step.

```r
exo    <- c("SPY", "CL=F")
naming <- c("SPY", "Crude")

out_exo <- map(exo, function(.x) {
  getSymbols(.x, from = "2010-01-01", to = Sys.Date(),
             src = "yahoo", auto.assign = FALSE) %>%
    xts_to_dataframe() %>%
    dplyr::select(1, 7) %>% # quickly select date and adjusted prices
    rename(Price = 2)
})
names(out_exo) <- naming

out_wide_exo <- out_exo %>%
  enframe() %>%
  unnest(cols = c(value)) %>%
  pivot_wider(names_from = "name", values_from = "Price")

weekly_returns_exo <- out_wide_exo %>%
  pivot_longer(cols = -date, names_to = "sector", values_to = "price") %>%
  mutate(week = floor_date(date, unit = "week")) %>%
  group_by(sector, week) %>%
  summarise(price_week_end = last(price), .groups = "drop") %>%
  group_by(sector) %>%
  arrange(week) %>%
  mutate(weekly_return = price_week_end / lag(price_week_end) - 1) %>%
  ungroup() %>%
  filter(!is.na(weekly_return)) %>%
  dplyr::select(week, sector, weekly_return) %>%
  pivot_wider(id_cols = week, names_from = sector, values_from = weekly_return) %>%
  mutate(Crude = ifelse(Crude <= -1, -0.5, Crude))
```

2.3 Combine and Filter

To produce a data frame quickly for illustration, portfolio and exogenous returns are joined on the week key and filtered to start from 2016, giving a cleaner estimation sample.

```
comb <- weekly_returns %>%
  full_join(weekly_returns_exo, by = "week") %>%
  mutate(across(where(is.numeric), ~replace_na(., 0))) %>%
  filter(week >= "2016-01-01")

returns_data <- comb %>% dplyr::select(-Crude, -SPY)
exo_data     <- comb %>% dplyr::select(week, Crude, SPY)

cat(sprintf("Portfolio : %d assets, %d weekly obs\n",
            ncol(returns_data) - 1, nrow(returns_data)))
```

```
## Portfolio : 10 assets, 536 weekly obs
```

```
cat(sprintf("Exogenous : %d instruments\n", ncol(exo_data) - 1))
```

```
## Exogenous : 2 instruments
```

```
# data structure of input data frames
head(returns_data)
```

```

3 Scenario 1: Base Case (Gaussian, Equal Weights)

The simplest possible call. No arguments are overridden: the function uses a multivariate Normal distribution, historical sample covariance, and equal weights across all ten assets. No stress is applied.

```
library(mcst)

result_1 <- portfolio_risk_simulation(
  historical_returns = returns_data
)
```

3.1 Fitted Marginal Distributions

Each panel shows the empirical return histogram with the fitted Normal density overlaid.

```
result_1$plots$portfolio_diagnostics$asset_distributions
```

Figure 1: Scenario 1: Fitted Normal marginals vs. empirical returns per asset.

3.2 Simulated Portfolio Return Distribution

```
result_1$plots$portfolio_diagnostics$portfolio_distribution
```

Figure 2: Scenario 1: Simulated portfolio return distribution (Gaussian, no stress).

3.3 Risk Metrics

Table 1: Scenario 1: Portfolio risk statistics (Gaussian base case).

Metric	Pre-Stress	Post-Stress
Mean (%)	0.4273	NA
Median (%)	0.4411	NA
Volatility (%)	2.9937	NA
Skewness	0.0141	NA
Excess Kurtosis	0.0496	NA
Sharpe (Annual)	1.0293	NA
Annual Return (%)	24.8225	NA
Annual Vol (%)	21.5876	NA
VaR 90% (%)	-3.3686	NA
VaR 95% (%)	-4.4897	NA
VaR 99% (%)	-6.5737	NA
CVaR 90% (%)	-4.8204	NA
CVaR 95% (%)	-5.7651	NA
CVaR 99% (%)	-7.5864	NA

3.4 Per-Asset Empirical Summary

Table 2: Scenario 1: Per-asset empirical return statistics.

Asset	Mean	SD	Skewness	Kurtosis	Min	Max
AXP	0.0040	0.0442	0.1545	10.2072	-0.2558	0.2883
BA	0.0030	0.0662	1.7068	33.6212	-0.4418	0.7051
JPM	0.0040	0.0374	-0.0035	7.4175	-0.1964	0.2226
LMT	0.0030	0.0327	0.2898	8.2515	-0.1409	0.1963
NGG	0.0019	0.0300	-0.5119	8.6672	-0.1667	0.1575

NVDA	0.0121	0.0637	0.3622	4.4982	-0.2005	0.3019
PG	0.0019	0.0244	-0.1781	5.7295	-0.1063	0.1140
TSM	0.0065	0.0420	0.2188	4.2185	-0.1393	0.1817
UAL	0.0034	0.0719	0.6876	12.2523	-0.4116	0.5125
XOM	0.0030	0.0384	-0.1108	6.6730	-0.2007	0.1674

4 Scenario 2: Fat Tails with t-Copula and EWMA Covariance

Changes from base case: Multivariate t returns (`rmvt`), t-copula to capture tail co-dependence, EWMA covariance ($\lambda = 0.97$) so recent observations receive higher weight, and per-asset degrees-of-freedom calibrated from the data (`calibration_method = "full"`).

```
result_2 <- portfolio_risk_simulation(
  historical_returns  = returns_data,
  sim_returns_dist    = "rmvt",
  cov_estimation      = "ewma",
  cov_lambda          = 0.97,
  calibrate_params    = TRUE,
  calibration_method  = "full",
  copula              = TRUE,
  copula_type         = "t",
  copula_df           = 4,
  n_sim_returns       = NULL,
  propagation         = TRUE,
  exogenous_returns   = NULL,
  exogenous_shock     = NULL,
  exogenous_volatility_shock = NULL,
  df                  = 4,
  seed                = 123
)
```

4.1 Tail Dependence and Copula Diagnostics

The left panel shows the pairwise lower tail dependence coefficient λ - the probability that two assets move to extreme values simultaneously. The right panel compares fitted copula correlations to the Kendall τ-implied starting values: points far from the diagonal indicate that MLE optimisation shifted that pair's correlation materially from the method-of-moments estimate.

```
result_2$plots$portfolio_diagnostics$tail_dependency
```

Figure 3: Scenario 2: Pairwise tail dependence and copula vs. Kendall baseline.

4.2 KS Uniformity Test

The KS test checks whether each asset's PIT residuals are Uniform[0,1] after the t-marginal is fitted. A rejection ($p < 0.05$) flags a misspecified marginal for that asset.

Table 3: Scenario 2: KS uniformity test on PIT residuals.

Asset	KS_stat	p_value	Flag
AXP	0.0673	0.0157	**REJECT**
BA	0.0988	0.0001	**REJECT**
JPM	0.0424	0.2896	**OK** |
LMT	0.0589	0.0486	**REJECT**
NGG	0.0519	0.1113	**OK** |
NVDA	0.0339	0.5694	**OK** |
PG	0.0489	0.1540	**OK** |
TSM	0.0364	0.4779	**OK** |
UAL	0.0708	0.0093	**REJECT**
XOM	0.0633	0.0271	**REJECT**

5 Scenario 3: Exogenous Volatility Shock - SPY Vol x2 (GJR-GARCH)

Shock: SPY volatility doubles ($k_{SPY} = 2$); Crude is unchanged ($k_{Crude} = 1$). No return shock is applied, so **portfolio means are unaffected** - only the covariance widens via the Law of Total Variance addon. GJR-GARCH estimates per-asset forward volatility, capturing volatility clustering and the leverage effect.

```
exogenous_volatility_shock <- list(SPY = 2, Crude = 1)
```

```
result_3 <- portfolio_risk_simulation(
  historical_returns          = returns_data,
  sim_returns_dist            = "rmvt",
  cov_estimation              = "garch",
  calibrate_params            = TRUE,
  calibration_method          = "full",
  copula                      = TRUE,
  copula_type                 = "t",
  copula_df                   = 4,
  n_sim_returns               = 10000,
  propagation                 = TRUE,
  exogenous_returns           = exo_data,
  exogenous_shock             = NULL,
  exogenous_volatility_shock  = exogenous_volatility_shock,
  df                          = 4,
  seed                        = 123
)
```

5.1 GJR-GARCH Conditional Volatility Paths

Each panel shows: salmon bars = raw returns; blue line = in-sample conditional $\hat{\sigma}_t$; red dashed = long-run unconditional $\bar{\sigma}$; green diamond = 1-step-ahead forecast. Assets where the forecast sits well above $\bar{\sigma}$ are in an elevated-volatility regime.

```r
result_3$plots$portfolio_diagnostics$time_series
```

Figure 4: Scenario 3: GJR-GARCH conditional volatility paths per asset.

5.2 Exogenous Propagation Channel

The beta $\beta_{pe} = \mathrm{Cov}(X_p, X_e)/\mathrm{Var}(X_e)$ quantifies the transmission of SPY volatility to each portfolio asset. With a pure vol shock (no return shock), these betas determine the size of the LTV covariance addon - not any mean shift.

```
result_3$stressed_plots$exogenous_propagation
```

Figure 5: Scenario 3: SPY propagation betas per portfolio asset.

5.3 Portfolio Distribution: Pre vs. Post Stress

```
result_3$stressed_plots$portfolio_distribution_comparison
```

Figure 6: Scenario 3: Portfolio return distribution, base vs. SPY vol x2.

5.4 Stress Impact Summary

Table 4: Scenario 3: Risk metric changes from SPY volatility doubling.

Metric	Pre_Stress	Post_Stress	Change
Expected Return (%)	0.4684	0.4454	-0.0230
Volatility (%)	3.7094	5.9755	2.2662
Skewness	-0.0294	0.0513	0.0807
Excess Kurtosis	1.1019	1.4197	0.3178
VaR 95% (%)	-5.5063	-9.2789	-3.7726
VaR 99% (%)	-8.6528	-14.1143	-5.4615
CVaR 95% (%)	-7.5005	-12.4326	-4.9321

6 Scenario 4: Oil Spike and Market Selloff (Exogenous Return and Vol Shocks)

Shock: SPY falls 5% ($\delta_{SPY} = -0.05$) with vol doubled; Crude surges 20% ($\delta_{Crude} = +0.20$) with vol doubled. This may simulate a stagflationary stress scenario: energy costs surge while equity markets sell off simultaneously.

Both return shocks enter the Schur complement together. The shocked block is $s = \{SPY, Crude\}$ and all portfolio asset means are updated by $\mu_{p|s} = \mu_p + \Sigma_{pe}\Sigma_{ee}^{-1}\delta_e$. Energy-sensitive holdings (XOM) received a net positive effect, whereby a positive effect from a high beta to Crude Oil is partially offset by a negative effect from SPY declines. Broad-market holdings (JPM, AXP, NVDA) are dominated by the SPY decline.

```
exogenous_shock            <- list(SPY = -0.05, Crude = 0.20)
exogenous_volatility_shock <- list(SPY = 2,     Crude = 2)
```

```
result_4 <- portfolio_risk_simulation(
  historical_returns          = returns_data,
  sim_returns_dist            = "rmvt",
  cov_estimation              = "garch",
  calibrate_params            = TRUE,
  calibration_method          = "full",
  copula                      = TRUE,
  copula_type                 = "t",
  copula_df                   = 4,
  n_sim_returns               = NULL,
  propagation                 = TRUE,
  exogenous_returns           = exo_data,
  exogenous_shock             = exogenous_shock,
  exogenous_volatility_shock  = exogenous_volatility_shock,
  df                          = 4,
  seed                        = 123
)
```

6.1 Propagation of the Compound Exogenous Shock

```
result_4$stressed_plots$exogenous_propagation
```

Figure 7: Scenario 4: Conditional mean shifts from SPY -5pct and Crude +20pct.

6.2 Portfolio Distribution Comparison

```
result_4$stressed_plots$portfolio_distribution_comparison
```

Figure 8: Scenario 4: Portfolio distribution under oil spike and market selloff.

6.3 Stress Impact Summary

Table 5: Scenario 4: Risk metrics under stagflationary shock.

Metric	Pre_Stress	Post_Stress	Change
Expected Return (%)	0.4684	-2.2174	-2.6857
Volatility (%)	3.7094	6.1009	2.3915
Skewness	-0.0294	0.0526	0.0820
Excess Kurtosis	1.1019	1.4224	0.3205
VaR 95% (%)	-5.5063	-12.1157	-6.6094
VaR 99% (%)	-8.6528	-17.1303	-8.4775
CVaR 95% (%)	-7.5005	-15.3732	-7.8727

6.4 Exogenous Historical Correlations

This table explains the propagation magnitudes above. Assets with high SPY correlation (JPM, AXP, NVDA) absorb the largest mean shift from the SPY leg; XOM's positive Crude correlation provides a partial offset.

Table 6: Scenario 4: Historical correlations, portfolio vs. SPY and Crude.

Asset	Crude	SPY
AXP	0.180	0.728
BA	0.182	0.627
JPM	0.188	0.717
LMT	0.217	0.469
NGG	0.049	0.451
NVDA	0.133	0.633
PG	0.017	0.488
TSM	0.092	0.552
UAL	0.036	0.565
XOM	0.526	0.467

7 Scenario 5: Semiconductor Selloff with SPY Offset (Mixed Endo and Exog)

Shock: NVDA and TSM each fall 5% with vol multiplied 1.5x (endogenous return and vol shocks). Simultaneously, SPY rises 2.5% with vol 1.25x (exogenous return and vol shock). This captures a sector-specific stress ie regulatory action or export controls on semiconductors that occurs against a mild broader market rally.

The Schur complement operates on a combined shocked block $s = \{NVDA, TSM, SPY\}$. Assets correlated with the semiconductor pair receive a negative propagated mean shift; the SPY tailwind partially offsets this for holdings with high market beta.

```
asset_shock                <- list(NVDA = -0.05, TSM = -0.05)
volatility_shock           <- list(NVDA = 1.5,   TSM = 1.5)
exogenous_shock            <- list(SPY = 0.025)
exogenous_volatility_shock <- list(SPY = 1.25)
```

```
result_5 <- portfolio_risk_simulation(
  historical_returns          = returns_data,
  sim_returns_dist            = "rmvt",
  cov_estimation              = "garch",
  calibrate_params            = TRUE,
  calibration_method          = "full",
  copula                      = TRUE,
  copula_type                 = "t",
  copula_df                   = 4,
  n_sim_returns               = NULL,
  propagation                 = TRUE,
  asset_shock                 = asset_shock,
  volatility_shock            = volatility_shock,
  exogenous_returns           = exo_data,
  exogenous_shock             = exogenous_shock,
  exogenous_volatility_shock  = exogenous_volatility_shock,
  df                          = 4,
  seed                        = 123
)
```

7.1 Mean Shift Decomposition (Waterfall)

The stacked bar chart decomposes each asset's total conditional mean shift into three components: (1) **direct endogenous shock** (non-zero only for NVDA and TSM), (2) **propagated from endo** (Schur from the NVDA/TSM block), and (3) **propagated from exog** (Schur from the SPY return shock). The diamond marker shows the net total.

```
result_5$stressed_plots$mixed_shock_effects
```

Figure 9: Scenario 5: Mean shift decomposition - direct endo, propagated endo, propagated exog.

7.2 Portfolio Distribution Comparison

Despite the SPY tailwind, the portfolio distribution shifts left because NVDA and TSM are large equal-weight components with high intra-sector correlations that propagate their decline across correlated holdings.

```
result_5$stressed_plots$portfolio_distribution_comparison
```

Figure 10: Scenario 5: Portfolio distribution - semiconductor selloff with SPY rally.

7.3 Stress Impact Summary

Table 7: Scenario 5: Risk metrics under semiconductor-specific stress.

Metric	Pre_Stress	Post_Stress	Change
Expected Return (%)	0.4684	-0.8664	-1.3347
Volatility (%)	3.7094	4.6541	0.9447
Skewness	-0.0294	0.0510	0.0804
Excess Kurtosis	1.1019	1.4295	0.3276
VaR 95% (%)	-5.5063	-8.3955	-2.8892
VaR 99% (%)	-8.6528	-12.2048	-3.5520
CVaR 95% (%)	-7.5005	-10.9243	-3.4238

8 Accessing Simulation Draws Directly

The raw per-asset simulated draws are stored as $n_{\text{sim}} \times n_{\text{assets}}$ data frames - accessible without any aggregation to portfolio level. This enables custom downstream analysis such as per-asset VaR.

```
draws_pre  <- result_5$asset_draws
draws_post <- result_5$asset_draws_stress

cat("Pre-stress  draws:", nrow(draws_pre),  "rows x", ncol(draws_pre),  "cols\n")
```

```
## Pre-stress  draws: 10000 rows x 10 cols
```

```
cat("Post-stress draws:", nrow(draws_post), "rows x", ncol(draws_post), "cols\n")
```

```
## Post-stress draws: 10000 rows x 10 cols
```

```
cat("Columns:", paste(names(draws_pre), collapse = ", "), "\n")
```

```
## Columns: AXP, BA, JPM, LMT, NGG, NVDA, PG, TSM, UAL, XOM
```

8.1 NVDA: Pre vs. Post Stress Simulated Distribution

```
nvda_comp <- data.frame(
  Return   = c(draws_pre$NVDA, draws_post$NVDA),
  Scenario = rep(c("Pre-Stress","Post-Stress"), each = nrow(draws_pre))
)

means_df <- nvda_comp %>%
  group_by(Scenario) %>%
  summarise(m = mean(Return * 100), .groups = "drop")

ggplot(nvda_comp, aes(x = Return * 100, fill = Scenario)) +
  geom_density(alpha = 0.45, colour = NA) +
  geom_vline(data = means_df, aes(xintercept = m, colour = Scenario),
             linetype = "dashed", linewidth = 0.8) +
  scale_fill_manual(values   = c("Pre-Stress" = "steelblue","Post-Stress" = "coral")) +
  scale_colour_manual(values = c("Pre-Stress" = "steelblue","Post-Stress" = "coral")) +
  labs(title    = "NVDA: Simulated Return Distribution, Pre vs. Post Stress",
       subtitle = "Scenario 5: NVDA direct shock -5%, vol x1.5 | SPY +2.5%, vol x1.25",
       x = "Weekly Return (%)", y = "Density", fill = NULL, colour = NULL) +
  theme_minimal(base_size = 11) +
  theme(legend.position = "bottom")
```

Figure 11: NVDA simulated return distribution, pre and post Scenario 5 stress.

9 Cross-Scenario Comparison

Table 8: Pre-stress portfolio risk statistics across all five scenarios.

Scenario	Mean (%)	Vol (%)	VaR 95% (%)	CVaR 95% (%)
S1: Gaussian, sample cov (no stress)	0.4273	2.9937	-4.4897	-5.7651
S2: t + EWMA + t-copula (no stress)	0.4577	2.4443	-3.4766	-4.8196
S3: t + GARCH, SPY vol x2	0.4684	3.7094	-5.5063	-7.5005
S4: t + GARCH, SPY -5pct / Crude +20pct	0.4684	3.7094	-5.5063	-7.5005
S5: t + GARCH, NVDA/TSM -5pct + SPY +2.5pct	0.4684	3.7094	-5.5063	-7.5005

Scenarios 3–5 show the pre-stress baseline. The incremental stress impact is captured in each scenario's stress impact summary table above.

10 Quick Reference: Result Object Fields

Table 9: Quick reference: result object fields and plot accessors.

Field	Description
result$portfolio_stats	14-row data frame: risk metrics pre and post stress
result$asset_draws	n_sim x n_assets data frame of pre-stress per-asset draws
result$asset_draws_stress	n_sim x n_assets data frame of post-stress per-asset draws
result$asset_empirical_summary	Per-asset empirical mean, SD, skewness, kurtosis, min, max
result$exogenous_historical_correlation	Portfolio x exogenous Pearson correlations (Asset + one col per instrument)
result$exogenous_asset_empirical_summary	Exogenous instrument empirical summary: mean, SD, skewness, kurtosis
result$ks_test	KS test results: Asset, KS_stat, p_value, Flag
result$stress_impact_summary	7-row data frame: Metric, Pre_Stress, Post_Stress, Change
result$stressed_covariance	n x n stressed covariance matrix after shock application
result$stressed_means	Named vector of stressed conditional means per asset
result$final_covariance	n x n final forward-looking covariance matrix
result$copula_correlation	n x n fitted copula correlation matrix
result$tail_dependence	n x n tail dependence matrix (t-copula only)
result$calibrated_params	Calibrated shape parameters per asset
result$plots$...$asset_distributions	Histogram + fitted density overlay, one panel per asset
result$plots$...$portfolio_distribution	Simulated portfolio return distribution (histogram + KDE)
result$plots$...$tail_dependency	Tail dependence bar chart + copula vs. Kendall tau scatter
result$plots$...$time_series	GJR-GARCH conditional vol time series (GARCH cov_estimation only)
result$stressed_plots$portfolio_distribution_comparison	Overlaid pre vs. post stress portfolio return distributions
result$stressed_plots$exogenous_propagation	Exogenous beta and propagation channel plots (Scenario B)
result$stressed_plots$mixed_shock_effects	Waterfall decomposition: direct + propagated endo + exog (Scenario C)

11 Sample Function Output: Console Printout

The `portfolio_risk_simulation` function produces a detailed diagnostic console printout during execution. This section captures a representative example from Scenario 4 (oil spike and market selloff) to illustrate what the output looks like, covering data preprocessing, copula fitting, stress-testing steps, and the final stress impact summary.

historical_returns converted from tibble to data frame Date column detected: 'week' (536 dates, 2016-01-03 to 2026-04-05) Data frequency inferred: Weekly (52 periods/year)
